ABSTRACTED NAVIGATIONAL ACTIONS FOR IMPROVED HYPERMEDIA NAVIGATION AND MAINTENANCE

Wilfried Lemahieu, K.U.Leuven, wilfried.lemahieu@econ.kuleuven.ac.be

ABSTRACT

This paper discusses the MESH framework, which proposes a fully object-oriented approach to hypermedia. Object-oriented abstractions are not only applied to the conceptual data model, but also to the navigation paradigm. This results in the concept of context-based navigation, which reduces the end user’s disorientation problem by means of dynamically generated, context-sensitive guided tours. Moreover, maintainability is greatly improved, as both nodes and links are defined as instances of abstract classes. In this way, single links and entire guided tours are anchored on type level as abstract navigational actions, which are independent of the actual link instances.

Keywords: hypermedia, navigation, guided tours, object-orientation

INTRODUCTION

The hypermedia paradigm looks upon data as a network of nodes, interconnected by links. Whereas each node symbolizes a concept, a link not only stands for a relation between two items, but also explicitly assumes the semantics of a navigation path, hence the quintessential property of navigational data access. Their inherent flexibility and freedom of navigation raises hypermedia systems as utterly suitable to support user-driven exploration and learning. Therefore, hypermedia data retrieval embraces a notion of location. Data accessibility depends on a user’s position in the network, denoted as the current node. Manipulation of this position gradually reveals links to related information [14]. Unfortunately, due to inadequacy of the underlying abstractions, most hypermedia technologies suffer from severely limited maintainability. Moreover, the explorative, non-linear nature of hypermedia navigation imposes a heavy processing load upon the end user, referred to as cognitive overhead. The stringent problem of cognitive overhead effecting into user disorientation and losing one’s chain of thought is known as the ‘lost in hyperspace’ phenomenon [7].

The benefits of data modeling abstractions to both orientation and maintainability were already acknowledged in [6]. They yield richer domain knowledge specifications and more expressive querying. Typed nodes and links offer increased consistency in both node layout and link structure [9]. Higher-order information units and perceivable equivalencies (both on a conceptual and a layout level) greatly improve orientation [17]. Semantic constraints and consistency can be enforced [1]; [5], tool-based development is facilitated and reuse is encouraged [15]. The first conceptual hypermedia modeling approaches such as HDM [4] and RMM [8] were based on the entity-relationship paradigm. Object-oriented techniques were mainly applied in hypermedia engines, to model functional behavior of an application’s components, e.g. Hyperstorm [2], Microcosm [3] and Hyperform [19]. Along with EORM [10] and OOHDM [16], MESH is the first approach where modeling of the application domain is fully accomplished through the object-oriented paradigm.

The MESH hypermedia framework as deployed in [11] proposes a structured approach to both data modeling and navigation, so as to overcome said maintainability and user disorientation
problems. MESH is an acronym for Maintainable, End user friendly, Structured Hypermedia. This paper briefly overviews MESH’s data model and navigation paradigm (for a more thorough discussion, we refer to [13] and [12] respectively). Subsequently, the concept of abstract navigational actions is explained in detail. As a conclusion, the approach is evaluated with respect to both orientation and maintenance.

THE MESH HYPERMEDIA FRAMEWORK

The basic concepts: node types, aspects, layout templates and link types

On a conceptual level, a node is considered a black box, which communicates with the outside world by means of its links. External references are always made to the node as a whole. True to the object-oriented information-hiding concept, no direct calls can be made to its multimedia content. However, internally, a node may encode the intelligence to adapt its visualization to the navigation context (cfr. infra). Nodes are assorted in an inheritance hierarchy of node types. Although the primary node classification mechanism is total, disjoint and constant, the aspect construct allows for defining additional classification criteria, which are not necessarily subject to these restrictions. Apart from a single "most specific node type", aspects enable a node to take part in other secondary classifications that are allowed to overlap or change over time (see [13] for further details). A child node type should be compliant with its parent’s definition, but may fine-tune inherited features and add new ones. These features comprise both node layout and node interrelations, abstracted in layout templates and link types respectively. A layout template is associated with each level in the node typing hierarchy, every template being a refinement of its predecessor. Its exact specifications depend on the implementation environment, e.g. as to the Web it may be HTML or XML based. Node typing as a basis for layout design allows for uniform behavior, onscreen appearance and link anchors for nodes representing similar real world objects.

A link represents a one-to-one association between two nodes, with both a semantic and a navigational connotation. A directed link offers an access path from its source to its destination node. Links representing similar semantic relationships are assembled into types. Link types are attributed to node types and can be inherited and refined throughout the hierarchy. Link type properties such as domain, cardinalities, destination and inverse allow for enforcing constraints on their instances. These properties can be overridden to provide for stronger restrictions upon inheritance. E.g. whereas an artist node can be linked to any artwork through a has-made link type, an instance of the child node type painter can only be linked to a painting, by means of the more specific child link type has-painted. Link types are deemed extremely important, as they not only enforce semantic constraints but also interface between nodes, such that these can be coded and updated independently of one another. Moreover, they provide the basis for context-sensitive node visualization (cfr. infra). Therefore, in MESH, specialization semantics can be enforced not only upon node types, but also upon the link types. A sub link type defines a type whose set of instances constitutes a subset of its parent’s, and which models a relation that is more specific than the one modeled by the parent, possibly with stronger constraints.

Guided tours derived from the current context

In conventional hypermedia applications, the current node is the only variable that determines which information is accessible at a given moment; navigation is only possible to nodes that are linked to this current node. Its value changes with each navigation step as it represents the
immediate focus of the user’s attention. MESH introduces the current context as a second, longer-term variable that ‘glues’ the various visited nodes together and provides a background about which common theme is being explored. The current context is defined as the combination of a context node and a context link type. The context node represents the subject around which the user’s broader information requirements ‘circle’. The nature of the relationship involved is depicted by the context link type. MESH builds upon its data model and the context notion to reconcile navigational freedom with the ease of linear navigation, by offering guided tours to a disoriented end user, chaining together all nodes pertaining to a common subject with forward/backward links. In contrast to the traditional guided tour notion [18], such guided tour is not static, but is adapted dynamically to the navigation context. E.g. the typical hypermedia links (represented as arrows) between Van Gogh and each of his paintings can be complemented by a guided tour (represented as dotted lines) along these paintings (figure 1).

A guided tour derives from the current context. Therefore, MESH discriminates between direct and indirect links. A direct link represents a lasting relation between two nodes. Direct links are typed and reflect the underlying conceptual data model. Because they are permanent and context-independent, they are stored explicitly into the hyperbase and are always valid. E.g. the node Sunflowers is directly linked to the Van Gogh node. An indirect link between two nodes indicates that they share relevancy to a common third node. The latter denotes the context within which the indirect link is valid. As indirect links not only reflect the data model, but also depend on a run-time variable, the current context, they cannot be stored within the hyperbase. They are to be created dynamically at run-time, as inferred from a particular context. E.g. an indirect link between Sunflowers and Wheatfield is only relevant when exploring information related to Van Gogh. A guided tour is defined as a path of indirect links along all nodes relevant to the current context. These nodes are directly linked to the context node (through instances of the context link type) and indirectly to their predecessor and successor in the tour. As they are chained into a linear structure, a logical order should be devised in which the subsequent tour nodes can be presented to the user. The most obvious criterion is in alphabetical order of a node descriptor field. More powerful alternatives are discussed in [11]. E.g. the context Van Gogh has-painted yields a guided tour among the nodes {Irises, Potato eaters, Starry night, Sunflowers, Wheatfield, …} with Van Gogh as the context node and has-painted as the context link type.

A general implementation architecture

in MESH, the information content and navigation structure of the nodes are separated and stored independently. The resulting system consists of three types of components: the nodes, the linkbase/repository and the hyperbase engine. In [11], a platform-independent implementation framework was provided, but all subsequent prototyping is explicitly targeted at a Web environment. A node can be defined as a static page or a dynamic object, using e.g. HTML or XML. Its internal content is shielded from the outside world by the indirection of link types playing the role of a node’s interface. Optionally, it can be endowed with the intelligence to tune its reaction to the context in which it is accessed, by integrating the node type’s set of attributed link types as a parameter in its layout template’s presentation routines (cfr. infra). Since a node is not specified as a necessarily searchable object, linkage information cannot be embedded in a
node’s body. Links, as well as meta data about node types, link types, aspect descriptors and aspects are captured within a searchable linkbase/repository to provide the necessary information pertaining to the underlying hypermedia model, both at design time and at run-time. This repository is implemented in a relational database environment. Only here, references to physical node addresses are stored, these are never to be embedded in a node’s body. All external references are to be made through location independent node ID’s. The hyperbase engine is conceived as a server-side application that accepts navigational commands from the current node, retrieves the correct destination node, keeps track of the current context and provides facilities for generating maps and overviews. Since all relevant linkage and meta information is stored in the relational DBMS, the hyperbase engine can access this information by means of simple, pre-defined and parameterized database queries, i.e. without the need for searching through node content.

ABSTRACT NAVIGATIONAL ACTIONS

Navigational actions in MESH can be classified according to two dimensions. First, there is moving forward and backward within the current tour, along indirect links. Second, and orthogonal to this, there is the option of moving up or down along direct links, closer to or further away from the session’s starting point. Additionally, one can distinguish between actions that change the current context and actions that only influence the current node. However, any of these movements can be specified as an abstract navigational action, i.e. independently of the actual link instance(s) involved. This feature will prove to be very advantageous to both navigation and maintenance.

Moving forward/backward within the current tour

Moving forward or backward in a guided tour along indirect links, results in the node following/preceding the current node being accessed to become the new current node. The current context remains unaffected (see figure 2). Such action can be specified (and anchored) as a simple “next” or “previous” command. The hyperbase engine calculates the correct destination node, based on the current node and the current context. Hence, the action can be specified unambiguously without referring to the actual link instance.

Moving up/down

Moving down implies an action of ‘digging deeper’ into the subject matter, moving away from the starting point. This is accomplished through selection of a direct link type from the current node. In the case of a unique destination node, the result is the latter node being accessed. In the case of a set of destination nodes, the outcome is a new “nested” tour being started. In traditional hypermedia navigation, selection of a link instance \( l \) from a given source node \( n_s \) results in its unique destination node \( n_d \) being accessed: \( n_s.l := \{n_d | l = (n_s, n_d)\} \). E.g. selection of the link (Sunflowers, National Gallery) from the current node Sunflowers, induces an access to the node National Gallery. This can be symbolized as Sunflowers.(Sunflowers, National Gallery) := {National Gallery}. However, MESH aggregating single link instances into link types, yields the opportunity of anchoring and consequently selecting a complete link type from a given source node. Selection of a link type \( L \) from a source node \( n_s \) yields a set of all destination nodes \( n_d \) of
tuples representing link instances of $L$ with $n_s$ as the source node, i.e. all nodes that are linked to the current node by the selected link type: $n_sL := \{n_d \mid (n_s, n_d) \in L\}$. Depending on maximum cardinality of the link type, the resulting set may be a singleton or may contain multiple destination nodes. E.g. selection of the unique link type exhibited-in from the current node Sunflowers, induces an access to the node National Gallery. The latter can be symbolized as Sunflowers.exhibited-in := \{National Gallery\}. The result is the same as with traditional hypermedia, only now, the action is specified by the link type instead of the actual link instance.

Selection of the non-unique link type reviews from the same current node Sunflowers generates a collection of nodes to-be-accessed: Sunflowers.reviews := \{review#1, review#2, review#3, ...\}. The result of such action is a context change: a new context emanates, resulting in new indirect links. A new guided tour is generated, nested within the former, according to this new context (figure 3). The new tour is completely specified by its context, i.e. the combination of the source node and a link type.

Again, such action can be identified unambiguously without referring to the actual link instances. The above entails that contexts and guided tours exist in layers. As such, it is possible to ‘delve’ into a subject and have multiple open tours, nested within one another, where the context node of one tour is the current node of the tour it is nested in. Navigation along indirect links is invariably carried out within the “deepest”, i.e. most recently started tour. Continuing a tour on a higher level is only possible if all tours on a lower level have been either completed or disbanded. The latter is accomplished by moving up, which reverses the latest move down action. If the latter involved a context change, the move up action results in the reestablishment of the previous context and the cancellation of the tour generated through this most recent link type selection. The previous context’s context node and indirect links are restored. The most recent context node (Sunflowers in the example) again becomes the current node. Obviously, this action doesn’t require the specification of a link instance either and can be identified by a simple command.

**Abstract navigational actions applied to a complete tour**

The way in which navigational actions are specified in MESH, allows for casting abstract navigational actions to a whole class of nodes, regardless of the actual instance they are applied to. In this way, selections of link types that exist at a sufficiently high level of abstraction can be imposed upon every single node belonging to a tour. E.g. in the context of Van Gogh.has-painted, a reviews link type selection can be issued once on tour level, with additional (nested) tours Irises.reviews, Potato_eaters.reviews, Starry_night.reviews etc. being generated automatically for each node participating in the Van Gogh.has-painted tour. If these tours in their turn include navigational actions on type level, a complex navigation pattern results, which can be several levels deep. Again, forward and backward links always apply to the current tour, i.e. to the open tour at the ‘deepest’ level. In addition, the abstract navigational actions and tour definitions sustain the generation of very compact tree-shaped overviews and maps of complete navigation sessions. In this respect, the move up and move down actions indeed correspond to moving up or down in the graph. The represented information can also be bookmarked, i.e. bookmarks not just refer to a single node but to a complete navigational situation, which can be resumed at a later time (see [11] for further details).
CONCLUSIONS

Improved maintainability

MESH’s object-oriented data modeling abstractions allow for hypermedia maintenance capabilities equaling their database counterpart; with unique object identifiers, monitoring of integrity, consistency and completeness checking, efficient querying and a clean separation between authoring content and physical hyperbase maintenance. MESH greatly improves node independence and maintainability by anchoring link types instead of link instances. Abstract navigational actions, both within the current tour and orthogonal to the current tour, can be unambiguously specified by the combination of the source node and a link type. The latter defines the context within which the action takes place, or the new context induced by the action. An anchor is defined as the association between a user interface event (e.g. clicking an underlined word, a button or a hot spot) and such action. Upon stimulation, it causes the current node to close and pass the corresponding link type as a return value to the hyperbase engine. The latter calculates the correct destination node. A unique link type is mapped to a unique destination node. A non-unique link type is mapped to a guided tour, of which the first participating node is accessed. Hence, anchors remain independent of actual link instances and can be defined once at the level of node type layout templates, instead of for each individual node instance.

Maintenance of the individual link instances does not affect the node’s internal properties. Links can be added or removed without affecting the anchor and, consequently, the node’s content. Guided tours do not require any maintenance nor design effort, as the author is not even engaged in their realization: they are calculated at runtime by means of linkbase queries by the hyperbase engine, according to the user’s actions. A last advantage of MESH’s emphasis on abstraction is the fact that the majority of the nodes’ properties can be defined on an aggregate level. Authoring is greatly facilitated because layout as well as attributed link types and anchors can be laid down at node type level. By means of inheritance and overriding, abstract specifications can be refined on more concrete levels of the typing hierarchy. Needless to say that specification of properties on an abstract level will also improve hyperbase consistency, which in its turn reduces cognitive overhead and, consequently, end user disorientation.

Facilitated orientation

Indeed, apart from the obvious benefit of a well-maintained hyperbase, the abstractions should permit a user to better understand the information presented in the hypermedia system. The use of higher-order information units, i.e. node and link types, allows for consistent layout and user interface features. Reflecting similarities between nodes and the representation of collections of nodes as (source node, link type) combinations, induces a stronger sense of structure and is to reduce cognitive overhead. Obviously, navigation is facilitated by the context-sensitive navigation paradigm providing run-time generated guided tours. Moreover, by acknowledging a node type’s set of attributed link types as a factor in its visualization, a node can provide an appropriate reaction to each context in which it may be accessed. Consequently, the user can be directed to the most relevant section(s) of the node’s information content in this particular context. Sub link types, modeling a more specific relationship between two nodes than their parent, potentially provoke a more specific reaction by their instances’ destination nodes. More details on this context-sensitive visualization principle can be found in [11]. Furthermore, through the specification of navigational actions on tour level, complex navigation patterns can
be applied to all nodes in a tour without additional effort. The abundance of meta-information as node, aspect and link types allows for enriching maps and overviews with concepts of varying granularity. A final benefit is the ability to bookmark a complete navigational situation in an utterly compact manner, with the possibility of it being resumed later on, from the exact point where it was left.
